# Abstract

Spectral and wavelet analysis were performed on a tree ring width time series obtained from a 2500 yr old cypress tree (*Fitzroya cupressoides*) from Costa del Osorno, Chile. The periods for analysis were selected at 95% confidence level. Both periodicities characteristic of solar activity and climatic variations were found in this tree ring width series. The 11 and 22 years solar cycle periods were present in tree ring data with a confidence level above 98%. This indicates the solar modulation of climatic variations is being recorded by the tree ring grown. However wavelet analysis shows that these are present only sparsely. Short-term variations, between 2–5 years, are also present in tree ring data, and are shown by wavelet maps to be a more permanent characteristic. This time scale is a signature of ENSO events. Long-term variations, above 200 years, are also present in tree ring data. The spectral analysis performed in this work shows that this species has the ability to record solar-ENSO variations that seems to be affecting the local environment of tree growth, and also that this region was influenced by ENSO events at least in the past 2500 yr interval covered by this study.

## 1. Introduction

ENSO has a very strong influence on the climate in the South America and through teleconnections it may cause climatic anomalies in remote locations of the world, as for example driving droughts in Africa and floods in North America (Neelin and Latif, 1998). Both Southern Brazil and Chile, regions studied in this work, have high annual positive anomalies precipitation in periods of El Niño (Dai and Wigley, 2000).

Tree growth rings have been used to reconstruct both past climate and solar variability (Dutilleul and Till, 1992; Hughes et al., 1982; Kurts et al., 1993). The growth of tree ring depends of the amount of water precipitation and of temperature. Thus it is expected that precipitation and temperature fluctuations caused by ENSO, and others temperature forcing mechanisms, could have recorded their signal in tree growth

EGU

ring. In the South America region, researches with tree ring chronologies were made in order to study climate records in samples from Chile and Argentina (Hughes et al., 1982).

5 A new methodology was developed by Rigozo (1998) to study the solar activity and  
others geophysical signals in tree ring samples. Rigozo (1998), Rigozo and Norde-  
mann (2000a), Rigozo et al. (2002, 2003, 2004a), Nordemann and Rigozo (2003) have  
identified the 11 year solar cycle in tree ring samples from Southern Brazil, using spec-  
tral analysis. ENSO signal on tree rings from Southern Brazil (Rigozo et al., 2003) and  
Chile (Rigozo et al., 2004b) have been investigated for the last 150 year interval. In this  
10 paper a case study of solar variability and climatic effects was performed on a Chilean  
cypress tree (ca. 565 AC-1991 AD) growth ring width time series using multitaper and  
wavelet spectral analysis in order to study the influence of solar activity and ENSO  
signals on tree growth ring from Chile during a very long period (2500 years).

## 2. Methodology

15 The tree ring width time series obtained from a 2556-yr cypress tree (*Fitzroya cupres-*  
*soides*) collected at Costa del Osorno (Lat.: 40° S; Long.: 73°50' W; Alt.: 1000 m),  
Chile in 1991. The *Fitzroya cupressoides* species is sensible to both temperature and  
precipitation (Lara et al., 2000) and one of its main advantages is that individual series  
are generally over 900 years, so they represent an excellent source for the study of  
20 low-frequency signals (Wolodarskyh-Franke et al., 2002).

An image of a polished section of this tree was scanned by one of the authors (N.R.  
Rigozo) at the Department of Botany, University of Chile at Santiago (with Dr Aravena's  
kind support). The growth ring time series were obtained from digitized images of an  
adequately polished slice side, by a method developed by us and named Interactive  
25 Treatment of Tree Ring Images – ITTRI (Rigozo, 1998). The errors on the determination  
of ring thickness were estimated as about 1 pixel/ring per sample. The main positive  
points of this method are its low cost (necessary equipment is only a microcomputer

and a scanner) and that it does not need chemical treatments, radioactivity or mass spectrometric measurements, as occurs in isotopic methods.

5 The obtained tree ring width time series is normalized in function of its variance in the final growth rate tree, by choosing a function representing the growth trend (exponential fit) for the initial growth rate (ca. 565–88 AD) and final growth rate tree (89–1991 AD).

### 3. Spectral analysis methods

10 In spectral analysis, the use of a single taper in a time series reduces much of the bias due to spectral leakage in the spectral estimator, however, it also reduces the sample size and causes information to be lost (Parks, 1987). Thomson (1982) introduced the idea of using multiple tapers to recover the information lost while still maintaining acceptable bias. The method is known as the Multiple Taper Method – MTM. The MTM uses orthogonal windows (or tapers) to obtain approximately independent estimates of the power spectrum and then combines them to yield an estimate. This estimate exhibits more degrees of freedom and allows easier quantification of the bias and variance trade-offs, compared to conventional Fourier analysis. The MTM has the ability to detect small amplitude oscillations in a short time series without the necessity of filtering the signal. It has also an internal statistical F-test (F distribution) to obtain the significance level of the periodicity found (Thomson, 1990).

20 The parameter that controls the compromise between low variance and low bias is the product time\*bandwidth (NW- number of windows or tapers). This is a resolution parameter directly related to the number of tapers used to compute the spectrum. As NW increases, there are more estimates of the power spectrum and the variance of the estimate decreases. However, the bandwidth of each taper is also proportional to the NW, so as NW increases, each estimate exhibits more spectral leakage (wider peaks) and the overall spectral estimate is more biased. For each data set a specific value of NW must be used (Thomson, 1982, 1990).

The wavelet transform is a powerful tool to analyze non-stationary signals which per-

mits the identification of main periodicities in a time series and the evolution of their respective amplitude, frequency and phase. The wavelet transform of a discrete data series is defined as the convolution between the data series and a scaled/translated version of a chosen wavelet function (Torrence and Compto, 1998; Percival and Walden, 2000).

By varying the wavelet time scale and interval, it is possible to construct a picture showing the amplitude variations for every periodicity. In this work, the complex Morlet wavelet analysis was used because it is the most adequate to detect variations in the periodicities of geophysical signals along time scales. The Morlet wavelet is a sine wave modulated by a classical Gaussian function (Torrence and Compto, 1998).

#### 4. Results

A study of the spectral signal was performed by multitaper analysis on the tree ring width time series (Fig. 1a) obtained from a 2556-yr old cypress tree (*Fitzroya cupressoides*) sampled in 1991. The growth rate shows a decreasing tendency for all the tree life with a clear growth rate decrease at about 100 AD which probably corresponds to a drastic (local/regional/global) change of environmental/meteorological/climatic conditions at that moment. Wolodarskyh-Franke et al. (2002) have observed in their chronology of 5666 years from a nearby region in Chile (Contao, 41°35'S, 72°30'W), a period with growth below the average from 100 BC to 200 AD, coincident with sharp decrease in tree ring width the observed in this work. Other nearby chronology from Ayacara was commented by these authors as presenting also the same trend, reinforcing the idea that there might be one or a combination of environmental factors (climate and or volcanism) which caused this reduction in growth. At present it is not possible to assess if this environmental factors was local/regional, but it does not seems probable to be a global one.

In order to remove this long trend, an exponential fit (white curve in Fig. 1a) is applied to tree ring width data and a tree ring detrended time series is obtained (Fig. 1b).

Interactive Discussion

It can be observed that this series shows highly variable character, but a long-term modulation can be seen even by visual inspection. The obtained tree ring width time series is normalized in function of the variance (Fig. 1c) in the final growth rate tree (88–1991 AD) by multiplying variances rate ratio (initial variance/final variance) by the width time series.

After removal of the long range tendencies, as above described, from tree ring time series, the spectral analysis is performed. Figure 2 shows the confidence level spectrum obtained by MTM. The presence of peaks at both lower and high frequencies suggests that this species, growing at high altitudes sites, is very responsive to longer and shorter periods and to climatic factors influencing growth patterns.

The statistical estimate of significance of the frequency registered in the growth rings, above 95% of confidence, has been calculated using the multitaper method (Fig. 3). This figure shows high periodicities at 511 yr and short periods at 30, 20, 11, 7, 6, 5, 4, 3 and 2 yr. It may be observed that there exist peaks, with a high statistical estimate, close to the 75, 22, 11 and 5.5 years. Assuming that these signals have a solar origin, it would appear that the length of the solar cycle over this period was between 9.8 to 13.1 years near the current average of 11.1 years obtained by Murphy (1990). The same result was observed also in tree rings by Murphy and Palmer (1992), who found during a 426 year interval around AD 177, a mean period of 10.5 years for the length of the “11-year” solar cycle. An equivalent result was observed by these authors, for the “22-year” solar cycle, who obtained for the length of this solar cycle in the tree ring index a value of between 19.4 to 23.9 years.

Figure 2 shows high statistical estimates for the short periods, this represents a strong response of the tree rings to environmental influences. Some of these observed periods present estimated statistical significance above 99%, as it is the case of 6.6, 3.5, 3.1, 2.5, and 2.0 years.

The wavelet analysis was performed after removing from the original series the long term tendency function obtained by exponential function fit (Fig. 1a). The results of the wavelet analysis on the detrended series are shown in Fig. 3 and 4, respectively

Interactive Discussion

for periods 2 to 2116 yr and 2 to 33 yr. Figure 3 evidences a strong period of 530 yr, sparse periodicities with variable amplitudes for periods between 530 yr and 11 yr. The enhancement of periods greater than about 100 yr correspond to the faster growth intervals from 100 BC to 120 AD seen in Fig. 1. In Fig. 4, the expected periodicity at about 11 yr (of possible solar origin) appears only sparsely. Periodicities between 3 to 6 yr clearly appear in the El-Niño domain but only after the growth decrease at 120 AD which was probably associated to permanent more severe environmental conditions and consequent greater sensitivity to external factors such as those induced by El-Niño.

## 5. Discussion

The long-standing suggestion that variations in the Sun’s total irradiance (the “solar constant”) on time scales of decades to millennia may have been the cause of long-term climate variations has been revived in recent years by spacecraft radiometric measurements (Wilson and Hudson, 1988) showing that the Sun’s total irradiance has varied more or less in phase with solar magnetic activity as measured by the sunspot number since peak of solar cycle 21 in 1980. As was originally pointed out by Eddy (1976), the Maunder minimum coincided roughly with one the coldest episodes of the Little Ice Age, when global temperatures have been estimated to have been 1 to 1.5°C colder than modern temperatures (Crowley and North, 1991; Bradley and Jones, 1993).

Thus, it may be thought that variations in the total irradiation from the Sun can induce variations in tree growth by some mechanisms which involve sun induced global and regional climatic variations and specific sensitivity of trees to ambient variations which intervene as limiting factors when in stress conditions.

Confirmation of ring width variations may be attributed, at least in part, to anomalous solar activity. Many early spectral studies failed to find any significant evidence of solar periodicities (La Marche and Fritts, 1972). However, recent spectral studies have shown strong evidences of a 11-year period in tree ring data. Murphy (1990) found

evidences of a 11-year solar signal in tree ring data from Australia, with a time lag of 3 years. He also found periods close to the 22-year and 75 year (Gleissberg cycle) solar cycles. We also found a period close to the 11 year-old solar cycle and a strong evidence of the signal of the 22-year cycle.

These same results were found by Kurths et al. (1993) in samples of Miocene trees from Germany, where they observed periods of 12.5 years and the second harmonic of 11 year cycle in 5.5 years. We observed the second harmonic solar cycle between 4.9 to 5.8 years in tree ring index from Chile. Rigozo (1998) also found periods of 11 years and 22 years of solar origin in two different tree ring chronologies obtained at Concórdia, southern Brazil, of 160 years (1837–1996) and of 200 years (1797–1996). Rigozo and Nordemann (2000b) also found periods around solar cycles of 11-year and 22-year in a tree ring chronology (1931–1996) obtained from 15 trees from São Francisco de Paula, southern Brazil.

This spectrum analysis (Fig. 2) also presents variations with periods of 3 to 7 years, this may be an indication of the response of the tree rings growth to the environmental conditions at their location. These results also show a non-stationary behavior of the local climatic conditions that could represent possible influences of El-Niño events and variations in the environmental conditions of the region where trees grew. Rigozo and Nordemann (2000a) observed in tree ring width time series many periods with weak amplitudes, between 2 to 7 years. Gray et al. (1992), in their model studies, have found a variation in the period of occurrence of El Niño events, between 3 and 7 years. Wiles et al. (1998) also have found evidences of El Niño events with periods between 3 and 7 years in tree ring time series.

## 6. Conclusions

The spectral analysis of tree ring data from Chile presented strong evidences for the 11-year solar cycle and the Hale cycle. We observed also the second harmonic between 4.9 to 5.8 years. The results found are in agreement with other record studies of

the solar activity in the past, such as the concentrations of the cosmogenic isotopes carbon-14 (Stuiver and Quay, 1980) and beryllium-10 (Beer et al., 1988), and of tree ring data from Formosa, Colorado, Australia, Germany and Brazil.

The short periods observed can be due the environmental influences and climatic.

5 The spectral analysis also presents variations with periods of 3 to 7 years, which are visible for some intervals. This may be an indication of the response of the tree rings growth to the environmental conditions at their location. These results show a non-stationary behavior of the local climatic conditions that may represent possible influences of El Niño events and the variations in the environmental conditions of the region  
10 where trees have grown up.

More studies of regional tree ring data, as this, become necessary to determine the relative importance of the solar influences in the Sun-Earth system, in the past, since tree rings are seemingly becoming an excellent proxy data base for solar variability.
